Our business is dependent on the sustainability of the oceans’ resources as the most efficient and environmentally sound way to feed a growing global population. We believe that sustainability is as much about feeding people as it is about managing the world’s natural resources. To that end, we work tirelessly with our global supply network to ensure a consistent supply of the products our customers demand, while protecting and replenishing our common resource: the ocean.
Farmed Or Wild?
Both Types Of Salmon Taste Good And Are Good For You

Summary:

Whether farmed or wild, salmon are tasty fish and a healthy protein choice. They look and taste nearly the same. Wild Pacific salmon are harved by fishing, mostly in the north Pacific from June through September. Frozen or canned wild salmon are available outside this period. Farmed Atlantic salmon are harvested under controlled conditions, and available fresh year-round, usually at lower prices than wild-caught fish.

Salmon are the second-most popular fish consumed in the United States. It tastes savory and earthy, yet slightly sweet, and is among the richest sources of long-chain omega-3 fats. It is also full of high-quality protein, vitamins and minerals.

Research shows that eating fish like salmon promotes healthy hearts and brain development. All types of commercial salmon are healthful to eat. The most readily available kinds in the U.S. are wild Pacific and farmed Atlantic salmon. Farmed and wild salmon are very similar in many ways.

Salmon FAQs

How do farmed and wild salmon differ?

Farmed and wild salmon are usually different species of fish. Most farmed salmon are Atlantic salmon, Salmo salar. Wild populations of Atlantic salmon are generally at very low levels, and their commercial harvest is limited. Farm-raised fish are hatched, raised and harvested under controlled conditions comparable to other farmed animals. Farmed Atlantic salmon are available year-round in fresh or frozen forms.

Most wild-caught salmon are one of five species of Pacific salmon. They are harvested by fishing with a variety of gear types, mostly in the north Pacific from June through September. Fresh wild Pacific salmon are available during this time. The rest of the year, frozen or canned wild salmon are available.

How are farmed and wild salmon similar?

Farmed and wild salmon have very similar nutrients. Atlantic salmon and Pacific salmon look similar on the outside. But between species and even within the same species, each type of salmon can have different flavors, textures and flesh color. How the fish is processed and handled can also dramatically influence these characteristics.

In taste tests between farmed and wild salmon, sometimes farmed salmon is preferred. Sometimes taste panels prefer wild fish. However, these taste tests often compare farmed and wild salmon of different species and are not really designed to tell the differences between the tastes of the farmed and wild versions of the same type of salmon.

Often, wild salmon is priced higher than farmed salmon. Especially when buying fish fillets, it can be hard to tell the difference between how farmed and wild salmon look. It may take DNA analysis to confirm the identity of the species. Species substitutions sometimes occur, either accidentally or through business practices that mislead consumers. Consumers should buy salmon from trustworthy retailers and restaurants with good reputations.

What does salmon eat?

For survival and growth, both farmed and wild salmon need a well-balanced diet of protein, carbohydrates, fats, vitamins, minerals and pigments. In the wild, salmon eat zooplankton and fish. About 4.50 kg of prey is needed to make 0.45 kg of wild salmon. This means wild salmon have a feed-conversion ratio (FCR) around 10:1.

Farmed salmon need the same well-balanced diet to live and grow. They are fed a combination of fishmeal, fish oil and other land-based protein sources. The FCR is around 1:1. However, it should be noted that the water content in live prey items is much higher than in feed.

Some nutrients in prey and feed are considered essential because fish are unable to make them, so they must come from the diet. One such nutrient is the orange pigment astaxanthin, which is in the same family of nutrients as vitamin A. It is a powerful antioxidant that is thought to be involved in the ovarian development, hatching, survival, growth and respiration of salmon. Astaxanthin is also what causes the reddish-orange color of salmon flesh.

The color of wild and farmed salmon can vary widely from red to orange-red, rose, pink and even white. The colors depend mostly on the amount of astaxanthin in the diet. Wild salmon get natural astaxanthin from the prey they eat. Farmed salmon get natural or added astaxanthin from the feed they eat.

How does eating farmed and wild salmon make people healthier?

Both farmed and wild salmon are healthful choices that are low in total fat and high in protein (Table 1). Both are rich in vitamins, minerals and omega-3s. In recent years, research has linked eating seafood to many health benefits throughout life.

Scientists have compared concerns with eating fish to concerns with limiting or avoiding fish. They found that the biggest risk is limiting or avoiding fish, which results in thousands of extra heart disease deaths per year and less than optimal brain development in children.

Is salmon safe to eat?

Most foods contain traces of substances other than nutrients. Scientists have compared concerns with eating fish to concerns with limiting or avoiding fish, which results in thousands of extra heart disease deaths per year and less than optimal brain development in children.

how do farmed and wild salmon differ?

Farmed and wild salmon are usually different species of fish. Most farmed salmon are Atlantic salmon, Salmo salar. Wild populations of Atlantic salmon are generally at very low levels,
Atlantic salmon, *Salmo salar*, are more closely related to brown trout than to the Pacific salmon of the genus *Onchorhyncus*. Atlantic salmon have been domesticated and selectively bred for many generations. The primary species used in fish farming, they are grown in net pens in nearshore coastal waters and are typically harvested at a weight of 3.6 to 4.5 kg and length of 73 to 76 cm.

Greatly reduced populations of wild Atlantic salmon still spawn in rivers on both sides of the Atlantic. Although historically of great commercial importance, today less than 1% of commercially available Atlantic salmon come from the wild.

Chinook salmon, *Oncorhynchus tshawytscha*, also known as king salmon, live from California, USA, to Japan, with successful new populations in the Great Lakes and New Zealand. Chinook is the largest and least abundant of the Pacific salmon species. Their average weight is about 9 kg, and they range from 76 to 100 cm in length. Small quantities of farmed Chinook salmon can be found in the marketplace.

Sockeye salmon, *Oncorhynchus nerka*, also known as red salmon, are an important commercial species in British Columbia, Canada, and Alaska, USA. Their bright red flesh is prized for canning and for fresh and frozen products. The average size of fish in the marketplace is approximately 2.7 kg and 91 cm in length.

Coho salmon, *Oncorhynchus kisutch*, also known as silver salmon, range from northern Baja California to Korea. The average weight is 4.5 kg, and they range from 63 to 89 cm in length. Only small quantities of coho salmon are farmed.

Pink salmon, *Oncorhynchus gorbuscha*, are also known as humpback salmon because of the large hump males develop during spawning season. Pink are the smallest but most abundant Pacific salmon, generally weighing 0.9 to 1.4 kg at a length of 76 cm. They live from Puget Sound to Russia. Most pinks are canned and tend to cost less than other types of salmon.

Chum salmon, *Oncorhynchus keta*, are also known as silver-bright, keta or dog salmon. The average weight is 3.6 kg, and they can grow to 68 cm long. They are relatively easy to farm, and large hatchery programs in Japan and southeast Alaska complement wild populations. Chum are harvested commercially in large numbers when they return to their release sites. Like the pink salmon, chums tend to cost less than other types of salmon. They are sold canned, smoked, fresh, and frozen.

### Summary:
Striped catfish have become an important fish for national food security in Bangladesh, especially for poor consumers. The catfish-farming industry in the country is dominated by relatively small-scale farms that produce fish primarily for local markets. Due to potential overproduction, large-scale producers will likely need to process and export about 25% of the current production to survive in the long term.

### Commercial Farming of Striped Catfish, *Pangasianodon hypophthalmus* (Pangasius), introduced from Thailand started about 1998 and expanded rapidly after 2000 in Myanmar, Bangladesh, and thousands more smaller-scale farms. About 70% of the commercial farms are less than 5 ha in area, 20% cover 5 to 10 ha, and only 10% are larger than 10 ha. Thus the industry is dominated by relatively small-scale farms, but only about 30% of the total production is of sufficiently high quality for export. Most of the production is marketed locally at a relatively low price.

### Development
When commercial farming of striped catfish started, the profit was very high, as the public initially confused the species with the scarce native catfish *Pangasianodon hypophthalmus*, which today retails for U.S. $4.6/kg. In 1994, the production cost of striped catfish was only $0.44/kg compared to a farm gate price of $1.76/kg, which was a major factor in the initial expansion of catfish farming in the country. Unfortunately, attempts to develop commercial culture of the native river catfish have been unsuccessful to date.

Total production of striped catfish reached 300,000 mt in 2008, which caused a market glut. The farm gate prices fell to U.S. $0.60-$0.68/kg – below the $0.73/kg cost of production – and about 30% of farmers stopped raising the fish. When the production in 2009 fell to 200,000-250,000 mt, the farm prices rose once more to a profitable $0.88-0.96/kg toward the end of 2009.

### Local Benefits
Striped catfish have become an important fish for national food security, especially for poor consumers because of its relatively low price compared to the major Indian carp rohu, *Labeo rohita*, which retails for about twice as much. Rohu grow well only in large ponds and take a much longer two years to attain the marketable size of 1.5 kg. Relatively poor farmers get in and out of striped catfish farming, reverting back to rice farming depending on the profitability of the fish and rice. Poor rice farmers who are unable or unwilling to farm fish can benefit from leasing or selling their land to fish farmers or be employed at large fish farms, which require several full-time workers per ha.

### Farming System
The catfish ponds are shallow with a depth of only 1.5 m. As they are constructed in low-lying rice land, they could not be deeper since draining would not be possible. Large commercial farms are filled with groundwater pumped from 100-m-deep tube wells. Although there are no government regulations concerning the use of groundwater, its level has remained unchanged after more than a decade’s pumping. One-third of the pond water...
